Abstract

Objective: High consumption of energy-dense foods has been linked to high energy intakes and excess weight gain. This study tested the hypothesis that high energy density of the total diet is associated with lower diet costs.

Design: Dietary intakes of 837 French adults, aged 18–76 years, were assessed using a dietary history method. Dietary energy density (MJ kg⁻¹) was calculated by dividing total energy by the edible weight of foods consumed. Daily diet cost (€ day⁻¹) was estimated using mean national food prices for 57 food items. The relationship between dietary energy density and diet cost at each level of energy intake was examined in a regression model, adjusted for gender and age.

Results: The more energy-dense refined grains, sweets and fats provided energy at a lower cost than did lean meats, vegetables and fruit. Within each quintile of energy intake, diets of lower energy density (MJ kg⁻¹) were associated with higher diet costs (€ day⁻¹).

Conclusion: In this observational study, energy-dense diets cost less whereas energy-dilute diets cost more, adjusting for energy intakes. The finding that energy-dilute diets are associated with higher diet costs has implications for dietary guidelines and current strategies for dietary change.

Energy-dense diets have been associated with higher energy intakes and may be related to excess weight gain1–6. Energy-dense foods are generally described as those that are high in fat, sugar or starch7,8. In contrast, fruit, vegetables and juices with a high water content are energy-dilute7,9. Energy-dense diets are those high in fats, sweets, fast foods and desserts, whereas energy-dilute diets are those with a high proportion of vegetables and fruit5,6. A recent Technical Report from the World Health Organization has linked high consumption of energy-dense foods to the global obesity epidemic7.

Dietary strategies for health promotion increasingly call for taxes or levies on energy-dense foods containing added sugars and fats10–12. The intent of fiscal and policy interventions is to limit the consumption of fats and sweets or to provide funds to promote alternative and healthier food choices. Reducing dietary energy density through the consumption of vegetables and fruit is one approach to the clinical management of body weight6,13. Among suggested strategies for obesity prevention at the population level are restricting the intake of energy-dense foods, promoting vegetable and fruit intakes, and the provision of economic incentives for the production and marketing of healthier food products7.

At this time, there are few observational studies relating diet composition to diet costs. We recently found in a group of French adults that freely chosen diets high in fruit and vegetables were associated with higher diet costs14. In a study of UK women, Cade et al.15 found that diet quality, largely measured by a composite index of fruit and vegetable consumption, was also associated with sharply higher diet costs. An observational study in Denmark has also shown that low-fat diets for children tend to cost more16. Computer modelling studies based on linear programming revealed that reducing diet costs led to a major reduction in the vitamin and mineral contents of the predicted diets17. However, there is no consensus on this issue. At least two intervention studies in the USA purport to show that nutrient-dense diets are not more expensive than lower-quality diets and may even cost less18,19. Likewise, an intervention study in American children showed that low-fat diets for children did not lead to increased food costs20.

Economic forces may hold the key to dietary change. In particular, energy-dense foods, high in added sugars and fat, are popular because they are palatable, convenient, and because they provide dietary energy at a very low cost. Our hypothesis was that dietary energy density and daily diet costs would be inversely linked, after adjusting for energy intakes. In other words, energy-dense diets may be associated with a net saving in diet costs to the consumer. This study therefore examined, for the first time, the relationship between dietary energy density and the estimated costs of freely chosen diets in a community study. Analyses were based on a French dietary dataset, merged with national food prices provided by the French government. Clarifying the relationship between diet quality, energy density and diet costs has implications for dietary guidelines and strategies for dietary change.

Methods

Survey design and dietary assessment

The Val-de-Marne dietary survey, conducted in 1988–89, used a two-stage cluster-design sampling procedure. A description of the sampling and interview techniques and other methodological details of the study have been published. The study was based on 12 of the 47 districts in the Department of Val-de-Marne that were selected by probability sampling, where the probability of selection was proportional to district size. In the second stage, 75 families per district were selected at random from area telephone directories. Of the 849 families contacted, 527 took part in the study (62% response rate). The present analyses were based on 837 adults aged 18 years (361 men and 476 women). Trained dietitians interviewed members of each household at home. Dietary intakes were estimated using a dietary history interview, based on daily intake data representative of a habitual diet over 6 months. Habitual food consumption at breakfast, lunch and dinner, and during snacks, was assessed in terms of frequencies (per week) and quantities consumed (i.e. portion sizes) in a manner similar to a food-frequency questionnaire. Each food consumed was assigned a food item and combination foods were desegregated into two or more food items. In particular, the fats used for cooking were counted separately, and added to the other fats consumed. Dietary intake data were then used to calculate daily amounts of 73 distinct foods and food groups, as well as water and five types of alcoholic beverage. The complete Val-de-Marne nutrient database, calculated by INSERM, has been published previously. The ethics committee of CNAM-Paris approved the study protocol.

Energy density

The present analyses were based on 57 of the 73 food items in the Val-de-Marne database. Drinking water and alcoholic beverages were excluded, as were 10 baby and infant formula products and other foods never consumed by adults. Foods consumed by less than 5% of the population, including low-fat soft cheese, fats and spreads, were excluded. The 57 food items are listed in Table 1.

The amounts consumed by each participant, estimated in grams per day, were used to calculate daily energy intakes. The edible portion of each food was taken into account in calculating diet weight. Dietary energy density (MJ kg\(^{-1}\)) was obtained by dividing energy intake by the estimated edible weight of all foods and alcoholic beverages consumed (excluding alcohol). As such, the calculation was analogous to method 2 of Cox and Mela and one of the methods previously used by Gibson. The weight of drinking water and non-caloric beverages is generally excluded from dietary energy density calculations.

Estimated diet costs

For each of the 57 food items in the database, we selected a single representative example that was the most (or one of the most) frequently consumed items in that particular category. The representative foods tended towards

the most available and least expensive, based on expert judgement. We were assisted in this task by the nutritionist who trained the dietitians for the Val-de-Marne survey. Mean national retail prices for year 2000 for each of the 57 items were provided by the French National Institute of Statistics (INSEE)²⁵. A column of prices in Euros (1 € = US$ 1.17 in June 2003) was then added to the Val-de-Marne food composition database.

The price of red meat was based on the price of frozen hamburgers, whereas the price of poultry was based on chicken breasts. The prices of hard cheese and soft cheese were based on the price of Emmental and Camembert cheeses, respectively. The price of potatoes, root vegetables and tomatoes was based on fresh potatoes, fresh tomatoes and fresh carrots, the price of peas and beans was based on canned peas, the price of pulses was based on dried lentils and the price of mixed vegetables was based on mixed canned vegetables. Using other and more recent surveys of dietary habits in France, we were able to verify a posteriori that the foods selected for pricing were effectively the most frequently or the most heavily consumed. The energy cost (in € MJ⁻¹) of each food item is provided in Table 1.

**Underreporting of energy intakes**

Self-reported dietary intakes are generally found to be 10–30% below minimum estimates needed for survival, as calculated from the basal metabolic rate (BMR) adjusted for age, gender, height and weight²⁹. However, there has not been any evidence of underreporting of macronutrients when they are expressed as a percentage of energy, and nutrient densities did not change appreciably when underreporters were excluded²⁹. As a ratio measure, dietary energy density (MJ kg⁻¹) is exactly analogous to nutrient density measures, such as percentage of energy from fat. Using the Goldberg cut-off method recently re-evaluated by Black³¹, we computed the energy intake/BMR ratio to be 1.08. Persons with reported ratios of energy intake/BMR < 1.08 were considered by this technique to be underreporters (n = 183). Their exclusion had no impact on dietary energy density values and did not affect the strength of any of the correlations reported below.

**Statistical analyses**

The relationship between dietary energy density and daily energy intake was first tested in a univariate regression model for the whole sample, and then for men and women separately. The complex relationships between energy intake, diet weight and diet cost were tested using multivariate regression analysis with diet cost as the dependent variable and energy intake and diet weight as independent variables, adjusting for age and gender. Following the nutrient density analogy, dietary energy density was not entered per se in the regression model. Instead, an interaction term, energy intake by diet weight, was included and considered the operational form of dietary energy density in the multiple regression analysis.

As noted above, underreporters were excluded from some analysis to test the robustness of the results. Finally, participants were split by quintiles of energy intake (MJ day⁻¹) and the relationship between dietary energy density and diet cost was assessed separately for each quintile in a regression model, adjusted for gender and age. Statview statistical software (Statview version 5; Abacus Concepts, Inc., Berkeley, CA, USA) and SPSS version 9.0 (SPSS Inc., Chicago, IL, USA) were used for analyses.

**Results**

Consistent with past observations³, dietary energy density (MJ kg⁻¹) was correlated with daily energy intake (MJ day⁻¹) in a univariate regression analysis (R² = 0.31, P < 0.0001). Adjustment for age and gender or the exclusion of underreporters did not change the strength of the association (R² = 0.31, P < 0.0001 in both cases).

Dietary energy density was positively correlated with percentage of energy from grains and from fats and sweets, and negatively with percentage of energy from fruit and vegetables and from dairy products. A Pearson correlation matrix of dietary energy density with intakes of selected food groups (as % of energy) is shown in Table 2. Although primarily driven by water, dietary energy density was not independent of the diet's macronutrient content. Pearson correlation coefficients also showed that dietary energy density was positively associated with percentage

*, P < 0.05; **, P < 0.01.
of energy from sugar ($r = 0.23; P < 0.01$) and fat ($r = 0.42; P < 0.01$) and negatively with percentage of energy from protein ($r = -0.50; P < 0.01$) and energy-adjusted values for fibre ($r = -0.59; P < 0.01$) and vitamin C ($r = -0.59; P < 0.01$). Meat, dairy products, vegetables and fruit have higher water contents, and therefore lower energy density, than do fats and sweets.

Multiple regression analyses were then conducted using diet cost as the dependent variable. The interaction term between energy intake and diet weight was negatively associated with diet cost in a model that also contained energy intake, diet weight, age and gender ($R^2 = 0.68, P < 0.0001$). Exclusion of underreporters did not change the strength of this association ($R^2 = 0.70, P < 0.0001$). That association suggested an inverse relationship between dietary energy density and diet cost that was analysed further using partial correlations within each quintile of energy intake. Figure 1 shows the univariate relationship between diet cost (€/day$^{-1}$) and energy density (MJ kg$^{-1}$) within each quintile of energy intake as well as the regression lines. At each level of energy intake, energy-dense diets cost less than energy-dilute diets.

**Fig. 1** Relationship between energy density and diet cost, showing regression lines within each quintile of energy intake, for men and women participants in the Val-de-Marne study.
Energy density and diet costs

The regression coefficients were significant at each level of intake, although the slope was flatter for the top quintile of energy intake. Adjustment for age and sex further strengthened the association within eachenergy intake quintile.

Discussion

The present results confirm past observations that the consumption of energy-dense diets is associated with higher energy intakes. The present results also confirm past observations that energy-dense diets tend to be those with a high proportion of fats and sweets, whereas energy-dilute diets are those with a higher proportion of dairy products, vegetables and fruit.

However, our data also reveal that, at each level of energy intake, higher dietary energy density was associated with lower diet cost. Dietary energy density is largely determined by the water content of foods. Since water contributes the bulk of food weight, it influences energy density of foods more than does any macronutrient. The costs of transport, storage and waste are higher for perishable fresh produce than for packaged energy-dense foods, which are dry and tend to have a stable shelf life. It is an irrefutable fact that, on a per kg basis, energy-dense foods are less costly than energy-dilute foods. At global market prices, refined sugar and vegetable oils provide as much as 80,000 kJ per dollar. In contrast, the cost per kg of energy-dilute fresh produce is higher by several thousand per cent. Likewise, it is clear from the present data that the energy cost of most food items in the fruit and vegetables group (except potatoes, nuts and dried pulses) was much higher than that of fats and sweets (Table 1).

The present study is the first to provide evidence for an inverse relationship between dietary energy density and estimated diet cost. However, there are important limitations. First, in the absence of food expenditure data, the model was based on national retail food prices. In effect, the model estimated what each diet cost, as opposed to what the consumer paid for it. There are several precedents for estimating diet costs using mean prices for purchased food items from area stores. In a UK study, direct monetary cost of the diet was calculated using average national prices from the 1995 National Food Survey and the Tesco home shopping catalogue. In order to estimate the costs of the French diet, we linked dietary intake data from a nutrition survey conducted in Val-de-Marne in 1988 with a current list of mean national food prices published by INSEE in 2000. The principal reasons for using the Val-de-Marne survey were sample size (n = 837), high quality of dietary data obtained through individual interviews with trained dietitians, and our previous experience with the dataset. There was also a good match between the foods included in the nutrient database and the foods included by INSEE in their published list of food prices. The disparity in time between data collection in 1988–89 and the use of 2000 food prices could not be avoided. However, French government agencies report that dietary changes between 1985–1990 and the present day were relatively minor, since the most profound shifts had already occurred between 1950 and 1985. Our estimate of a daily diet cost of around 5 € per day was remarkably close to the mean national expenditure for food at home as calculated by INSEE from the National Budget Survey, i.e. 4.9 € per person per day.

Given that both obesity and type 2 diabetes follow a socio-economic gradient, there is an urgent need for further analyses of the association between diet quality, dietary energy density and diet cost. Future studies should be based on more recent dietary data and a more precise evaluation of diet costs or actual food expenditures. However, since the present model has produced such striking results, it is likely that the inverse association between dietary energy density and energy costs will only be confirmed in further studies.

The observation that energy-dense diets cost less has important policy and political implications. According to Engel’s law, the proportion of disposable income spent on food increases as incomes drop. In the general population, consumers select foods on the basis of taste, cost and convenience, and to a lesser extent on health and variety. However, among low-income households and the unemployed, cost and taste are the key determinants of food choice. Although food prices affect everyone, the issue of food cost as a barrier to dietary change is particularly relevant to low-income families. This may explain why the consumption of healthy diets rich in fruit and vegetables is so low among groups with low education and incomes.

The present results support the recently raised hypothesis that the links observed between poverty and obesity in industrialised societies are related to the low cost and high palatability of energy-dense diets.

The present observational studies do not speak directly to the cost of dietary change following nutritional interventions. Nutrition education programmes in the USA, aimed at the low-income consumer, include the Expanded Food and Nutrition Education Program (EFNEP) and the Food Stamp Nutrition Education Program (FSNEP). These programmes provide individual instruction on how to identify low-cost nutritious foods, how and where to make food purchases, and how to store and prepare the foods. However, the recommended diets, while meeting dietary guidelines, may be low on palatability and convenience, being composed of potatoes, rice, beans, pasta, ground turkey and frozen orange juice.

However, there is a dissociation between dietary recommendations and guidelines and the simple economics of the food supply. Energy-dense foods – often containing refined grains, added sugars and fats – are...
palatable, easily accessible, convenient and inexpensive.\(^{89}\) For many low-income consumers they may have become the norm. Insisting that the public consumes more costly diets high in lean meat, whole grains and fresh vegetables and fruits\(^{60}\) is economic elitism that can only generate frustration and culpability among the poor and less educated. This may account for the consumer backlash observed among these groups and directed against diet and health messages\(^{57}\). There has also been reluctance among lower-income groups to change dietary behaviour in response to a dietary information campaign\(^{58}\).

A focus on the economics of food choice is greatly overdue. Studies on the obesity epidemic and the contribution of snacks, fast foods, foods away from home and the phenomenon of supersizing\(^{8,59,60}\) have not addressed the very low energy costs of added sugars and fat. Among suggested strategies for reducing the consumption of energy-dense foods are taxes, levies, limits on advertising and outright bans\(^{10-12}\). Whether such punitive tactics will steer lower-income consumers toward more costly food choices is an unresolved issue. There is a need for additional studies on diet structure and food costs on which to base responsible nutrition interventions and fiscal food policy.
